ABSTRACT

Gene trap mutagenesis is a powerful tool to create loss-of-function mutations in mice and other model organisms. Modifications of traditional gene trap cassette, including addition of conditional features in the form of Flip-escision (FIEx) arrays to enable directional gene trap cassette inversions by Cre and Flp site-specific recombinases, greatly enhanced their experimental potential. By taking advantage of these conditional gene trap cassettes, we developed a generic strategy for generating conditional mutations and validated this strategy in mice carrying a multipurpose allele of the Prdm16 transcription factor gene. We demonstrate that the gene trap insertion creates a null mutation replicating the Pierre Robin sequence-type cleft palate phenotype of other Prdm16 mutant mice. Consecutive breeding to Flpe and Emx1IREScre deleter mice spatially restricted Prdm16 loss to regions of the forebrain expressing the homeobox gene Emx1, demonstrating the utility of the technology for the analysis of tissue-specific gene functions.

KEY WORDS: Conditional gene trap, Cleft palate, Mandible, Micrognathia, Pierre Robin sequence

INTRODUCTION

To better understand human development and disease, the role of single genes must be examined in the context of the entire organism. Efforts to expand our understanding of molecular mechanisms involved in human development and disease require the systematic analysis of gene function in model organisms such as mice. The availability of the mouse genome sequence and strong conservation of human and mouse genes have made mouse models an excellent tool for studying the phenotypic consequences of altered gene expression. A variety of strategies have been employed to introduce specific alterations into the mouse genome. Of these, chemical mutagenesis using N-ethyl-N-nitrosourea (ENU) and gene targeting or trapping in mouse embryonic stem (ES) cells has been used extensively in ‘forward’ and ‘reverse’ genetic screens, respectively (Stottmann and Beier, 2010). By exploiting site-specific recombinase systems such as Cre/loxP and Flpe/Frt in combination with gene targeting or trapping, it became possible to induce spatially and/or temporally controlled mutations in the mouse for functional studies (Bradner and Dymecki, 2004; Lao et al., 2012).

Gene trapping is an unbiased, high-throughput approach for inducing loss-of-function mutations and is performed with gene trap vectors that simultaneously mutate and report the expression of the targeted gene at the site of insertion (Kitajima and Takeuchi, 1998; Stanford et al., 2001). Classic gene trap vectors comprise a strong 5’ splice acceptor (SA) site, a promoterless reporter and/or selectable marker gene and a 3’ polyadenylation site, which are traditionally introduced into mouse ES cells via electroporation or viral infection to randomly insert throughout the genome. If insertion occurs into an intron of an expressed gene in the correct reading frame, the endogenous transcript is terminated by the gene trap’s polyA site, resulting in a fusion transcript from which the reporter is translated along with a truncated and non-functional version of the endogenous protein. Traditional gene traps induce null mutations and require a minimum level of endogenous gene expression for event selection (Friedel and Soriano, 2010; Friedrich and Soriano, 1991). To add conditional features to gene trap vectors, Schnütgen et al. (2005) equipped a series of gene trap vectors with flip-escision (FIEx) arrays that enable directional gene trap cassette inversions by Flp and Cre recombinases (Schnütgen et al., 2005). Because these gene traps generate multipurpose alleles enabling a variety of post-insertional modifications, they have been used extensively in combination with gene targeting or trapping by the International Knockout Mouse Consortium (IKMC) in an effort to conditionally mutate every protein coding gene of the mouse genome (Bradley et al., 2012). To pursue a gene of interest by taking advantage of the gene trap features to simultaneously inactivate and report gene expression at the insertion site, Friedel et al. (2005) used homologous recombination to introduce gene trap cassettes into a pre-specified gene, a strategy referred to as ‘targeted trapping’.

Here, we describe a mouse transgenic strain carrying a Prdm16 multipurpose allele created by the targeted insertion of the conditional gene trap cassette FlipROSA26geo* into the second intron of Prdm16. PRDM16 is a transcription factor whose inactivation has severe developmental consequences. It was first identified as an oncogene activated in cases of myelodysplastic syndrome and acute myeloid leukemias (Mochizuki et al., 2000). Loss-of-function Prdm16 mutations were shown to affect brown adipose cell fate, and hematopoietic and neuronal stem cell maintenance, and have been linked to the cardiomyopathy developing in patients with 1p36 deletion syndrome (Aguilo et al., 2011; Arndt et al., 2013; Chuikov et al., 2010; Seale et al., 2008, 2007). Our group and others have demonstrated a role for...
*Prdm16* during mandible and palate development. Its mutational inactivation in mice causes cleft secondary palate (CP) by a similar mechanism as seen in Pierre Robin sequence (PRS)-type clefting (Bjork et al., 2010; Warner et al., 2007). PRS is evident in humans exhibiting micrognathia and glossoptosis, which are palate-extrinsic factors that precipitate the development of cleft palate (Tan et al., 2013).

We demonstrate that the targeted insertion of the gene trap induces a null mutation that can be rescued and re-induced in pre-specified cells and tissues by consecutive matings to *Flpe* and *Cre* deleter mice. By simultaneously mutating and reporting gene expression at the insertion site, the strategy seems ideally suited for the analysis of tissue-specific gene functions at the organismal level.

**RESULTS**

**Vector design and targeted trapping of *Prdm16* in ES cells**

Plasmid vectors were designed to facilitate the efficient generation of targeted trapping constructs comprising a FlipROSAβgeo* gene trap cassette and *Prdm16*-specific homology arms (Friedel et al., 2005; Komada et al., 2000; Schnüttgen et al., 2005). A modified MultiSite GATEWAY cloning approach modeled after previous work described by Ikeya et al. (2005) was used (Fig. 1B). Three Entry clones [5’ and 3’ genomic homology arm clones and the FlipROSAβgeo* clone (Schnüttgen et al., 2005)] as well as one Destination clone (a modified gene targeting plasmid) were constructed, each containing appropriate attachment (att) sites to allow in vitro site-specific recombination to produce the desired gene targeting construct. 5’ and 3’ homology arms of ~5.8 kb and ~2.8 kb, respectively, were PCR-amplified using oligonucleotide primers containing specific att sites at their 5’ ends using the MICER clone MHPN 168g07, which contains an ~5 kb genomic DNA insert derived from the 129S5 mouse strain, as template DNA (Adams et al., 2004). These purified att-site-flanked PCR products were recombined with GATEWAY Donor clones (pDONR-P4-P1R and pDONR-P2R-P3) in in vitro Clonase reactions to generate 5’ and 3’ homology arm Entry clones (pENTR-5’HOM and pENTR-3’HOM). Highly conserved genomic sequences contained within each clone were sequenced to verify the integrity of the amplified

**Fig. 1. Overview of cGT vector construction and generation of the targeted multifunctional *Prdm16cGT* null allele.** (A) Schematic representation of the multifunctional gene trap cassette adapted from Schnüttgen et al. (2005). Colored arrowheads flanking the βgeo* fusion gene represent wild-type (wt) and mutant pairs of Frt (Frt and f3) and loxP (loxP and lox5171). (B) Schematic representation of the multi-fragment GATEWAY recombination strategy used to generate targeted trapping constructs to produce multifunctional gene trap alleles in the mouse. The method employs PCR amplification of 5’ and 3’ genomic homology regions (HR) using primers that contain appropriate att sites for site-specific BP Recombinase reactions with GATEWAY Donor (DONR) plasmids to produce 5’ and 3’ HR Entry (ENTR) plasmids. These plasmids are combined with a third ENTR clone that contains the reading-frame-specific prsFlipROSAβgeo* multifunctional gene trap cassette and a modified pPNT gene targeting plasmid converted for use as a GATEWAY Destination (DEST) plasmid in in vitro LR Recombinase reactions. The result was the final targeted trapping plasmid containing the multifunctional gene trap cassette flanked by 5’ and 3’ HRs in the pPNT plasmid backbone. Red and black arrows depict the oligonucleotide primers used to amplify across the recombination junctions for screening of bacterial transformants for verification of the desired targeting construct (F1/R1, F2/R2 and F3/R3). (C) Homologous recombination of the multifunctional cGT gene trap cassette into the *Prdm16* locus within intron 2. Oligonucleotide primers used for screening G418-resistant ES clones by RT-PCR (to identify trapped *Prdm16* cGT fusion transcript) or genomic PCR (to confirm correct targeting at the 5’ and 3’ homology regions (HRs)) are depicted along with the expected product sizes. (D) Confirmation of ES clones c16 and c54 by RT-PCR from ES clone total RNA (left) and PCR amplification from ES clone genomic DNA (right). Clone c60 was positive via RT-PCR screening; however, the correct 5’ and 3’ genomic products were not detected. pA, polyadenylation; SA, splice acceptor.
DNA fragments and guard against the possibility of introducing functional sequence variants upon ES cell targeting. The FlipROSAβgeo gene trap cassettes (prsFlipROSAβgeo) were modified to obtain three plasmid variants allowing reading frame continuity to be maintained from upstream exons through to ROSAβgeo (Schnütgen et al., 2005) (Fig. 1A,B). These modified gene trap cassettes included heterotypic Frt/F3 andloxP/loxS171 recombinase target sites flanking the βgeo* gene trap cassette (Schnütgen et al., 2005, 2008). The original Prdm16cGT allele produced the CP mutant phenotype in homozygous newborn pups and showed a β-galactosidase (βgal) expression pattern at embryonic day (E)10.5 similar to endogenous Prdm16 in developing craniofacial primordia, forebrain, hindbrain, heart, limbs and dorsal root ganglia (Fig. 2A). We also confirmed that no Prdm16 transcripts including exons downstream of the gene trap insertion existed in Prdm16cGT/cGT mutants, as demonstrated by RT-PCR amplification from total RNA isolated from wild-type (wt), heterozygous and homozygous mutant embryos (Fig. S1). Next, we crossed Prdm16cGT+/+ males to homozygous Flpe [Gt(ROSA)26Sortm1(FLP1)Jb4] deleter mice maintained on an FVB/NJ strain background (Farley et al., 2000). As anticipated, double heterozygous mice for the Prdm16cGT and Flpe deleter alleles exhibited gene trap cassette inversion. We will refer to the Flpe inverted cGT allele as cGTinv (Prdm16cGTinv). Prdm16cGTinv heterozygous mice were subsequently bred to FVB/NJ mice to segregate the cGTinv and Flpe alleles. Heterozygous Prdm16cGTinv/+/ mice were bred to homozygosity and maintained by homozygous matings. As expected, cGT inversion restored Prdm16 and abrogated βgeo* expression, and, most importantly, Prdm16cGTinv/cGTinv homozygous pups exhibited no abnormal phenotypes (Fig. 2B). To induce the original gene trap mutation, we crossed homozygous Prdm16cGTinv/cGTinv to βAct-Cre [FVB/N-Tg(ActB-cre)2Mrt/J] deleter mice (Lewandoski et al., 1997). Double heterozygous mice for the Prdm16cGTinv and Cre alleles exhibited gene trap cassette inversion. We will refer to the Cre inverted cGT allele as cGTreinv (Prdm16cGTreinv). Prdm16cGTreinv/+ heterozygous mice were subsequently bred to FVB/NJ mice to segregate the cGTreinv and Cre alleles and were maintained in an FVB/NJ background by successive outcrosses. Heterozygous Prdm16cGTreinv/cGTreinv mice were intercrossed to produce homozygous Prdm16cGTreinv/cGTreinv embryos or pups with reinserted cGT cassettes. Fig. 2C shows that Prdm16cGTreinv/cGTreinv newborn pups developed CP and re-expressed βgeo*, indicating that the original gene trap mutation could be readily reinduced by Cre-mediated cassette inversion. Overall, we obtained three strain variants carrying the original cGT, the Flpe inverted cGTinv and the Cre reinserted cGTreinv alleles, which demonstrated that the cGT cassettes are invertible from mutating to non-mutating configurations and back by the consecutive in vivo application of Flpe and Cre recombinases.

**Gene trap reporter expression recapitulates endogenous Prdm16 expression**

To further validate the Prdm16 gene trap alleles, we performed X-gal stainings on whole-mount E10.5 and E13.5 Prdm16Gt683Lex [positive control, harboring a conventional gene trap integration in intron 1 of Prdm16 (Zambrowicz et al., 2003, 1998)], Prdm16cGT, Prdm16cGTinv and Prdm16cGTreinv embryos as well as on postnatal day (P) 0 brains. We compared the βgal expression pattern of homozygous Prdm16Gt683Lex embryos to the patterns exhibited by the cGT allelic variants. Prdm16Gt683Lex E10.5 embryos showed strong staining in the developing forebrain, craniofacial prominences, heart, limbs, hindbrain and dorsal root ganglia (Fig. 3A). Consistent with mutating and non-mutating gene trap configurations, the βgal expression pattern of Prdm16cGT and Prdm16cGTreinv/cGTreinv embryos was comparable to Prdm16Gt683Lex embryos, whereas Prdm16cGTinv/cGTinv embryos showed no βgal expression.
expression (Fig. 3E,I,L). At E13.5 βgal expression in non-craniofacial tissues of Prdm16<sup>Gt683Lex</sup> and Prdm16<sup>cGT</sup> embryos reflected endogenous Prdm16 expression (Bjork et al., 2010) (data not shown). When the inferior maxilla and secondary palate region were examined in more detail, Gt683Lex homozygotes showed strong staining in the nasal cartilage upper incisor and molar mesenchyme, secondary palate and inner ear (Fig. 3B). Prdm16<sup>cGT</sup> or Prdm16<sup>cGTreinv</sup> embryos exhibited a similar βgal expression pattern except for in the secondary palate, where βgal was not detectable by X-gal staining (Fig. S1). SA, splice acceptor. Scale bars: 1 mm.

To characterize the gene trap expression pattern further, we performed X-gal staining on sectioned Prdm16<sup>Gbt683Lex</sup> and Prdm16<sup>cGT</sup> embryos at E14.5 (Fig. 4). We again compared Prdm16<sup>Gbt683Lex</sup> heterozygous embryos to both heterozygous and

---

**Fig. 2. In vivo functional validation of the Prdm16<sup>cGT</sup> multipurpose allele.** The conditional gene trap (cGT) cassette orientation and recombination endpoint within Prdm16 intron 2 is depicted on the left with the X-gal staining pattern and palate phenotype shown to the right for each cGT allelic variant (A-C). Note that the same X-gal-stained images used for comparisons in Fig. 3 are included here to illustrate the general βgal expression pattern observed for each cGT allelic variant.

(A) Schematic of the cGT allele produced by targeted trapping in ES cells (left). Strong X-gal staining in craniofacial tissues, forebrain, hindbrain, dorsal root ganglia, limb and heart is shown in E10.5 embryos to the right along with the cleft secondary palate (CP) evident in the inferior view of the maxilla in P0 homozygous mutant heads with mandibles removed (right). (B) Schematic of the outcome from crossing the cGT allele to FLPe deleter mice to induce ubiquitous and germine Fip-mediated site-specific recombination (SSR) between like Frt or F3 Fip recombinase target sites to produce the inverted, untrapped conditional allele (referred to as cGT<sup>inv</sup>). Intermediate recombination events in which deletion of one Frt and one F3 site occurs are not depicted (Schnütgen et al., 2005). This allows the inversion to be stabilized even with continued or renewed Fip exposure. To the right, absence of X-gal staining and CP in cGT<sup>inv</sup> homozygotes confirms the return of endogenous Prdm16 expression and trap inactivation. This strain is used in combination with Cre-expressing mouse strains for conditional Prdm16 ablation studies. (C) By crossing mice that carry the cGT<sup>inv</sup> allele to Cre-expressing BAcl-cre deleter mice, re-inversion of the gene trap cassette occurred between loxP or lox5171 Cre-recombinase target sites. This reconstituted the ‘trapped’ orientation of the cGT cassette (referred to as cGT<sup>reinv</sup>) and left a single loxP and lox5171 flanking the gene trap cassette, which stabilized this inversion. Strong X-gal staining is again observed in craniofacial tissues, forebrain, hindbrain, dorsal root ganglia, limb and heart as shown in E10.5 embryos, and the CP phenotype is evident in P0 homozygous mutants. Wild-type (wt) and cGT alleles are genotyped using oligonucleotide primers in the genomic sequence immediately flanking the cGT cassette and primers at the 5′ end of the βgeo<sup>*</sup> fusion gene or within the βGH 3′ polyadenylation (pA) signal (Fig. S1). SA, splice acceptor. Scale bars: 1 mm.
Fig. 3. Comparison of βgeo* gene trap reporter expression in Prdm16<sup>Gt683Lex</sup> and Prdm16 cGT, cGTinv and cGT<sub>reinv</sub> alleles. X-gal-stained Prdm16<sup>Gt683Lex</sup> (Lex) embryos and tissues are shown in the first row (A-D), followed by Prdm16<sup>cGT</sup> (E-H), Prdm16<sup>cGTinv</sup> (I-K) and Prdm16<sup>cGTreinv</sup> (L-O). Homozygous E10.5 and E13.5 embryos are compared in columns 1 and 2, followed by heterozygous and homozygous P0 brains. All embryos and whole brains were stained following consistent X-gal staining conditions. Comparison of E10.5 homozygous embryos showed consistency in X-gal staining pattern and intensity in craniofacial tissues, forebrain, hindbrain, dorsal root ganglia, limb and heart between Lex, cGT and cGT<sub>reinv</sub> embryos (A,E,L) with the expected absence of reporter expression in homozygous cGT<sub>inv</sub> embryos (I). Inferior views of E13.5 embryonic heads with mandibles removed exhibit gene trap allele-specific reporter expression pattern differences. Lex homozygotes (B) show strong staining in nasal cartilage, primary and secondary palate, incisor teeth mesenchyme, inner ear and hindbrain choroid plexus (not shown), whereas cGT and cGT<sub>reinv</sub> heads (F,M) showed staining in the nasal cartilage, primary palate, incisor teeth mesenchyme, inner ear and fourth ventricle choroid plexus with reduced intensity and, surprisingly, no obvious staining in the secondary palate shelves is evident. In cGTinv homozygotes (J), some unexplained background X-gal staining is observed, along with strong staining in the fourth ventricle choroid plexus. Note that the images in E, I and L are also shown in Fig. 2 to represent X-gal staining patterns observed in the three Prdm16 cGT allelic variants. Scale bars: 1 mm.
homozygous Prdm16cGT embryos. In Prdm16cGT/cGT heterozygotes, strong X-gal staining was observed in the forebrain cortex, hippocampus and choroid plexus as well as in the eye, nasal epithelium, palate, molar mesenchyme, tongue and Meckel’s cartilage (MC). In heterozygous Prdm16cGT/+ embryos, minimal X-gal staining was observed, whereas, in homozygotes, only those structures showing the strongest staining in Prdm16Gt683Lex/+ stained positive for βgal, including the fourth ventricle choroid plexus (cp) (B,J), molar tooth mesenchyme, and nasal cartilage (nc) and epithelium (ne) (C,D and K,L); however, regions of weaker staining show absence of βgal activity in cGT homozygotes (i.e. secondary palate shelves in A,C and I,K). Arrows in B and J depict nerve ganglia in the medulla oblongata. Additional abbreviations: Meckel’s cartilage (MC), palate shelves (p), primary palate (pp), molar teeth (m), incisor teeth (i), tongue (T) and nasal septum (ns). Scale bars: 500 µm.

Phenotypic characterization of Prdm16cGT mutants

The phenotype of Prdm16cGT and Prdm16cGTreinv mice was virtually identical with the previously reported Prdm16Gt683Lex and Prdm16csp1 phenotypes (Bjork et al., 2010). Homozygous mutants exhibited fully penetrant wide CP due to failed palate shelf elevation and died shortly after birth due to respiratory failure and abdominal distention. Heterozygous Prdm16cGT and Prdm16cGTreinv/+ mice showed a low incidence of CP. We extensively characterized the craniofacial phenotype of the Prdm16 gene trap mutants by histology, skeletal preparations and micro-computed tomography (µCT) scanning. To date, these analyses failed to identify phenotypic differences between mice that carry the Prdm16cGT or Prdm16cGTreinv alleles (data not shown); therefore, we used them interchangeably for the characterization of the Prdm16 null phenotype. Overt CP was evident in P0 pups (Fig. 2A,C), whereas failed palate shelf elevation and tongue flattening was observed much earlier in coronal sections through Prdm16cGT/cGT heads (Fig. 4G,K). Moreover, MCs were smaller and rounder in Prdm16cGT/cGT mutants (Fig. 4K) compared with Prdm16Gt683Lex/+ and Prdm16cGT/+ heterozygotes (Fig. 4C,G). To examine craniofacial bone and cartilage morphology, we stained P0 and E15.5 Prdm16cGTreinv/cGTreinv mutants and wt controls with Alcian Blue for cartilage and Alizarin Red for bone (Fig. 5). Mutant heads were reduced in size at P0 and micrognathia was observed by gross examination and µCT scanning as well as in skeletal preparations (Fig. 5A-F,Q,R). Moreover, µCT scans showed reduced ossification of the frontal and parietal bones, although this was less obvious in skeletal preparations and nasal cartilage appeared shortened, together with the nasal and pre-maxilla bones (Fig. 5A-D,Q,R). Consistent with the phenotype of the other
Fig. 5. Prdm16<sup>GT</sup> mutants exhibit defects affecting the craniofacial skeleton. (A-H) P0 skeletal preparations of an unaffected heterozygous (A,C,E) and mutant (B,D,F) head from the same litter stained with Alizarin Red and Alcian Blue; lateral (A,B), dorsal (C,D) and inferior (E,F) views. Abnormalities in the craniofacial skeleton are evident in a general reduction in size of the skull, hypoplasia of the nasal capsule and nasal cartilage (black arrowhead in C,D), mandible (black arrowheads in A,B), tympanic rings (white arrowheads in A,B and E,F) and failed fusion of the palatine bone (white arrows in E,F). (G,H) Magnified view of the lateral tympanic rings illustrate the dramatic hypoplasia and thickening of the superior aspects of the rings in heterozygotes versus mutants (white arrowheads). Malleus and incus exhibit delayed ossification. (I-L) Dissected mandibles and hyoid bones from the same P0 pups. Obvious hypoplasia of the ventral mandible, especially in the anterior aspects where an abnormal curvature is observed, is indicated by the arrows in I and J. No defects in the hyoid bone are evident. This micrognathic phenotype is evident in lateral views of the bisected mandible bone as well (K,L). This anterior shortening accompanies the observation that incisor teeth are reduced in size in mutants as well (K,L). (M-P) Skeletal preparations of E15.5 wild-type (wt; M,O) and mutant (N,P) embryonic heads. Hypoplasia of the mandible is again evident in both lateral (M,N) and ventral (O,P) views and depicted by black arrows. Reduced ossification of the frontal and parietal bones is also observed. (Q-T) Lateral µCT images of wt (Q,S) and mutant (R,T) P0 heads illustrate the micrognathia (black arrowheads in Q,R), hypoplastic tympanic rings and nasal capsule, and decreased ossification seen in homozygous mutants (R) compared to wt controls (Q). The nasal capsule is dysmorphic and the nasal and pre-maxillary bones are hypoplastic and show reduced ossification as well. Inferior view of the maxilla illustrates the failed fusion of the palatine processes that demonstrates clef secondary palate (CP) in mutants (black arrows in S,T), which makes the vomer (v) and presphenoid (ps) bones visible in mutants. Parietal bone (pr), frontal bone (fr), nasal bone (na), nasal cartilage (nc), pre-maxilla (pmx), hyoid bone (Hy), incisor tooth (i), coronoid (cor), condylar (cond) and angular (ang) processes of the mandible, external pterygoid process (ePP) and internal pterygoid process (iPP), palatine process (pp) and maxillary process (mp), malleus (M), incus (I), Meckel’s cartilage (MC), tympanic ring (TR). Scale bars: 2 mm, except for G,H, which are 1 mm.
Prdm16 mutants (Bjork et al., 2010), Prdm16<sup>GT<sub>cGT<sub>inv/cGT<sub>inv</sub>\textsuperscript{+}</sup></sub> mice were first outcrossed to Gt(Rosa)26Sor<sup>minDym</sup> (RC::epe) mice expressing a lox-mCherry-lox-GFP reporter transgene from the Rosa26 locus (Purcell et al., 2009). Carriers of both alleles were bred to homozygosity to obtain Prdm16<sup>GT<sub>cGT<sub>inv/cGT<sub>inv</sub>\textsuperscript{+}</sup></sub>; RC::epe double homozygous offspring (Fig. 6). The RC::epe allele directs expression of mCherry in any cell not exposed to Cre recombinase. By excising mCherry from the transgene reporter, Cre induces GFP expression accurately reflecting the sites of Cre expression (Fig. 6B).

As shown in Fig. 7A-C, Cre-negative E13.5 heterozygous Prdm16<sup>GT<sub>cGT<sub>inv/cGT<sub>inv</sub>\textsuperscript{+}</sup></sub>; RC::epe/+; Emx1::cre/+ embryos developed strong βgal expression in the forebrain, which overlapped with GFP expression (Fig. 7D-F), indicating that gene trap inversion was restricted to the sites of Cre expression. Fig. 7H,I show that this expression persisted in P0 mutant embryos.

PRDM16 expression overlaps with that of the neural progenitor marker SOX2 (Hutton and Pevny, 2011) in multiple neural progenitor cell zones of the E13.5 wt brain (Fig. S2), including the ventricular zone (VZ) and SVZ, the ganglionic eminence (GE) and the hippocampus (HI). Additionally, PRDM16 is strongly expressed in the choroid plexus (CP), where SOX2 is absent. To test whether the spatially restricted gene trap inversions also abolish endogenous Prdm16 expression, we visualized PRDM16 along with SOX2 in P0 brain sections by immunostaining. Fig. 8A-F shows overlapping PRMD16 and SOX2 expression in all three surfaces of the lateral ventricle (LV) in brains of heterozygous Prdm16<sup>GT<sub>cGT<sub>inv/cGT<sub>inv</sub>\textsuperscript{+}</sup></sub>; RC::epe/+; Emx1::cre/+ controls. However, PRDM16 was depleted from the dorsal and medial surfaces of the LV of homozygous Prdm16<sup>GT<sub>cGT<sub>inv/cGT<sub>inv</sub>\textsuperscript{+}</sup></sub>; RC::epe/+; Emx1::cre/+...
brains, which closely correlate with the GFP expression pattern (Fig. 8A′-F′,E). Taken together, these results validate the targeted trapping approach as a promising and highly adaptable tool for conditional mutagenesis in mice.

We also examined cell proliferation and apoptosis in our forebrain-specific mutant brains in light of the previous study in Prdm16G658Llex mutant newborns that found reduced cell proliferation and increased apoptosis in the forebrain (Chuikov...
et al., 2010). We used anti-Ki67 and anti-Caspase-3 antibodies to examine cell proliferation or apoptosis, respectively, and observed no obvious differences in our experiments (data not shown).

Interestingly, Prdm16cGTinv/cGTinv; RC::epe+; Emx1::cre/+ conditional mutants survived to adulthood without obvious gross morphological defects in the brain. However, preliminary histological assessment of the forebrain in these mutants identified heterotopias, possibly resulting from impaired neuronal migration (data not shown). It should be noted that Prdm16 is only depleted from select regions of the developing forebrain, and its expression in other areas of the brain remains unaffected. By contrast, Prdm16Gt683Lex mutants represent a complete null condition and therefore exhibit more profound defects. Given the broad expression of PRDM16 in multiple brain regions, it is reasonable to speculate that cell non-autonomous effects from loss of Prdm16 at other brain regions may contribute to impaired neural stem cell self-renewal and increased apoptosis observed in the VZ of Prdm16Gt683Lex mutants.

**DISCUSSION**

The present study described a conditional mutagenesis approach enabling mammalian gene functional studies in a spatially and temporally restricted manner. The approach takes advantage of a gene trap amenable to directional inversions by Flpe and Cre recombinases at the insertion sites (Schnütgen et al., 2005). Introduced into a gene of interest by targeted trapping in ES cells that are subsequently converted into mice, the gene trap can be switched from mutagenic to non-mutagenic configurations by breeding to Flpe or Cre deleter mice. Although the potential of this gene trap for inducing conditional mutations has been known for some time, the present experiments show for the first time that its targeted insertion enables conditional ablation of a pre-specified gene. By using a multi-fragment GATEWAY recombination strategy, we generated targeted trapping constructs for the Prdm16 gene in as little as 2 weeks. Mice derived from the targeted ES cells readily recapitulated the phenotypes described previously for ENU (Prdm16csp1) and gene trap (Prdm16Gt683Lex) Prdm16 mutations (Bjork et al., 2010).

Homozygous FlipROSAβgeo gene trap mutants exhibited CP and micrognathia, reminiscent of the PRS-type cleft palate, as well as gross morphological defects affecting the eye, lungs, heart and brain (data not shown). Conditional ablation of Prdm16 in the brain of homozygous Prdm16Gt683Lex newborn pups that underwent Emx1IREScre-mediated gene trap re-inversion revealed PRDM16 loss in the forebrain that could be accurately mapped to the dorsal and medial surfaces of the lateral ventricle by the simultaneous visualization βgeo* (X-Gal staining) and Cre (GFP) expression. By using Prdm16Gt683Lex mice on a background carrying the RC::epe GFP Cre-reporter allele, we could clearly associate loss of PRDM16 in the forebrain with Cre expression and gene trap re-inversion with βgeo* reporter gene expression (Fig. 7). As the forebrain-specific Prdm16 mutants are viable and in light of the heterotopic forebrain phenotype, they could be used for the analysis of late-onset behavioral and motor coordination phenotypes along with further assessment of associated morphological changes and molecular mechanisms. Heterotopias are commonly observed in...
various neurological conditions, including epilepsy (Andrade, 2009; Fry et al., 2013). Moreover, by crossing to other tissue-specific Cre-drivers, Prdm16 gene trap mice can be used to dissect the function of Prdm16 in brown adipose differentiation, hematopoiesis or neurogenesis, just to name a few of the pleiotropic consequences of Prdm16 null mutations (Aguilo et al., 2011; Chuikov et al., 2010; Kajimura et al., 2008; Seale et al., 2008, 2007). From a developmental standpoint, the conditional Prdm16 mutants will be useful to dissect the anatomic and molecular mechanisms underlying the craniofacial abnormalities.

There have been extensive efforts by the IKMC to mutate every single protein-coding gene in ES cells by homologous recombination (Skarnes et al., 2011). Launched in 2003, the project has created a repository of mutant ES cells, most of them conditionals, for nearly 18,000 genes. However, while enabling spatially and temporally controlled knockouts, the IKMC targeted alleles lack a reporter. This complicates mutation mapping to specific cells and tissues by requiring target-protein-specific antibodies, of which many are unsuitable for immunohistochemistry. By providing a reporter, FlipROSAgeo alleles circumvent this need, as the mutations can be directly mapped by simple X-gal staining. Since reporters are exchangeable, replacing geo with fluorescent reporters, such as those used in this study, may simplify mutation mapping even further. Overall, we strongly believe direct visualization of mutation sites as shown here for the Prdm16 gene trap mutants embodies a considerable advantage for the characterization of conditional mutations in the mouse.

Although the gene trap cassettes were introduced into the genome by out-of-date technology, it is easily conceivable to use the CRISPR/Cas9 system instead, and in particular the recently reported by out-of-date technology, it is easily conceivable to use the mouse.

**Conditional gene targeting GATEWAY Destination vector**

We converted the traditional gene targeting vector, pPNT (Tybulewicz et al., 1991) into the pPNT-DEST-R4-R3 GATEWAY Destination plasmid by replacing the Neo' cassette with a PCR-amplified attR4-ccdB-Cm'-attR3 cassette of pDEST-R4-R3 vector. In brief, pPNT was digested with NotI and Xbal and CIP-treated followed by gel purification. The attR4-ccdB-Cm'-attR3 cassette was amplified using Pfu DNA polymerase and oligonucleotide primers oBB 1054 and oBB 1055 containing 5' PspOMI and Nhel sites, respectively. The product was PCR-purified (Qiagen), digested with PspOMI and Nhel and ligated to the digested gel-purified pPNT vector backbone to create pPNT-DEST-R4-R3. Ligations were transformed into chemically competent DB3.1 E. coli cells (Invitrogen - Life Technologies) and grown on LB agar plates supplemented with kanamycin.

**Construction of conditional gene trap targeted trapping vector**

The three Entry clones, pENTR-5'-Hom, pENTR-3'-Hom and prsFlipROSAgeo* TT0-ENTR11, and the pPNT-DEST-R4-R3 Destination vector were combined to create the final targeted trapping vector via the in vitro Multisite GATEWAY recombination system using LR Recombinase Plus enzyme following the manufacturer’s protocols (Invitrogen - Life Technologies). Plasmid DNA was isolated using the QIAprep Spin Miniprep Kit (Qiagen). The final ~19 kb targeted trapping vector, prsFlipROSAgeo*Prdm16in2, was transformed into chemically competent Sbi3 E. coli cells and grown on LB agar plates supplemented with ampicillin. Primers spanning 3 of 4 recombination junction sites were used to screen transformants (pUC_F/fobB 1067, oBB 1069/965 and oBB 1073/hsvdk_R, Fig. S1 and Table S2), and positive clones were verified using restriction mapping.

**Construction of conditional gene trap targeted trapping vector**

Invitrogen - Life Technologies.

The promoterless gene trap depends upon endogenous Prdm16 expression in ES cells to confer G418 resistance, so titrations of G418 concentrations were tested to determine optimal levels. For our experiment, 125 μg/ml G418 was sufficient to allow correctly targeted ES cells to survive, while still killing most incorrectly targeted ES cells.

To identify correctly targeted ES cell colonies, total RNA was extracted using Trizol Reagent and used as template in One-Step RT-PCR assays using primers oBB 1116 and oBB 1125 to amplify a predicted 360 bp product and identify the desired Prdm16-geo* fusion gene trap transcript (Fig. 1C,D; Invitrogen - Life Technologies). Of the 80 ES cell lines resistant to 125 μg/ml G418, two were PCR-positive. Genomic DNA extracted from RT-PCR-positive ES clones were screened for desired recombination events using primers (oBB 1112/1113) designed near the 3' end of the gene trap cassette and outside the 3' homology arm sequence and Pfu Ultra II Fusion HS DNA Polymerase (Stratagene) to generate a 3.3 kb PCR product in correctly targeted clones (Fig. 1C,D). Correct 5' targeting was verified only in ES clones that were positive by RT-PCR and the 3' targeting event. These primers (oBB 1114/1115) were designed near the 5' end of the gene trap cassette and outside the 5' homology arm sequence and yielded a 6.1 kb product (Fig. 1C,D). Correctly targeted ES cells containing the cGT cassette insertion into Prdm16 intron 2 were microinjected into C57BL/6J blastocysts (Brigham & Women’s Hospital, Partners Healthcare Transgenic Core facility, Boston, MA). Germline chimeras were obtained and crossed to Prdm16geo* mice (Bjork et al., 2010) for complementation testing or FVB/NJ mice to monitor germline transmission. Germline transmission was confirmed by failure to complement the csp1 mutation, agouti coat color in...
heterozygous progeny from the FVB/NJ outcross and confirmation by PCR genotyping to identify the Prdm16<sup>GT</sup> allele. This Prdm16<sup>GT</sup> allele is available on request. All animals were housed in accordance with Harvard Medical School (HMS) or Midwestern University (MWU) Animal facility regulations, and all studies were performed consistent with protocols approved by the HMS or MWU Institutional Animal Care and Use Committees.

Genomic DNA isolation and genotyping
Genomic DNA was isolated from individual embryos and weaned mice using a modified ‘HotSHOT’ protocol (Truett et al., 2000). A total of 2 μl of the ~500 μl supernatant was used as template for allele-specific PCR genotyping assays. Allele-specific genotyping assays were designed to differentiate the cGT alleles. Oligonucleotide primers outside the cGT cassette (proximal, oBB 1086; distal, oBB 1087) were paired with primers located at the 5′ end of the βgeo<sup>+</sup> fusion gene (oBB 1115) or within the bovine growth hormone (bGH) 3′ polyadenylation signal (oBB 1112). Use of one flanking genomic primer paired with the two internal primers will yield a product of a specific size dependent upon the orientation of the gene trap cassette at the locus (Fig S1). Primers specific for the wt Prdm16 allele (oBB 1086/1087), trapped Prdm16<sup>GT</sup> and Prdm16<sup>GT</sup>inv gene trap alleles (oBB 1087/1112) or untrapped conditional Prdm16<sup>GT</sup>T<sub>inv</sub> allele (oBB1087/1115) were used (Fig. 2 and Table S2). Amplified products were electrophoresed through 2% agarose gel and documented using a ChemiDoc Imaging System (Bio-Rad Inc.). oBB 1086/1087 amplifies the wt allele only and yields a 370 bp product. oBB 1087/1112 is specific for the trapped orientation of the cGT cassette and yields the following products in the various allelic variations due to deletion of loxP or Frt sites during intermediate site-specific recombination events: cGT<sup>−</sup>274 bp, cGT<sup>−</sup>inv=NA, cGT<sup>T</sup>inv=508 bp. Similarly, oBB 1087/1115 amplifies only the inverted conditional cGT<sub>inv</sub> allele and yields the following products: cGT=NA, cGT<sub>inv</sub>=603 bp, cGT<sub>inv</sub>=<sub>T</sub>inv=NA. The products amplified become smaller with each inversion event, since Frt or loxP sites are lost from the cGT cassette by the stable endpoint of Cre- or Flpe-mediated recombination (Schnüttgen et al., 2005). Genotype status of embryos or mice derived from forebrain-specific ablation studies was determined by the combination of GFP expression, cGT allele genotyping PCR and the presence of the Cre allele (oBB 1324/1325; Table S2). In addition, to identify conditional mutants, we screened for absence of the oBB 1086/1087 wt allele, thus demonstrating the presence of two cGT cassettes in these animals. The other allele-specific assays served as amplification controls against these ‘no amplification’ samples being the result of dirty, dilute or degraded DNA.

Conditionality of the gene trap
Stable inversion and re-inversion of the conditional gene trap occurred as described (Schnüttgen et al., 2005). Male heterozygous carriers of the cGT allele (Prdm16<sup>GT</sup>′) were crossed with mice homozygous for the Flpe<sup>[FVB/N-Gt(Rosa)26Som<sup>Alb</sup>Flp1Dym]</sup> deleter allele maintained on an FVB/NJ strain background (Farley et al., 2000). Subsequent Flpe-positive, Prdm16<sup>GT</sup>′<sub>T</sub> carriers were outcrossed to FVB/NJ to segregate the Flpe allele. Prdm16<sup>GT</sup>′<sub>T</sub> carriers of the next generation carried the inverted Prdm16<sup>GT</sup>T<sub>inv</sub> conditional allele. We bred the 129Sv-Gt(Rosa)26Som<sup>Alb</sup>D<sub>ym</sub> (RC::cre) Cre reporter allele (Purcell et al., 2009) into this strain and intercrossed the resulting double heterozygous males and females to double homozygous males to produce Prdm16<sup>GT</sup>T<sub>inv</sub>/+; RC::epe+; Emx1<sup>CreEScre</sup> homozygous males to produce Prdm16<sup>GT</sup>T<sub>inv</sub>/+; RC::epe+; Emx1<sup>CreEScre</sup> triple heterozygotes. Male mice of this genotype were backcrossed to the Prdm16<sup>GT</sup>T<sub>inv</sub>/+; RC::epe+ females to carry out the conditional ablation cross. Forebrain-specific ‘conditional mutants’ (Prdm16<sup>GT</sup>T<sub>inv</sub>/+, RC::epe+; Emx1<sup>CreEScre</sup>+) and Cre-positive ‘conditional heterozygote’ controls (Prdm16<sup>GT</sup>T<sub>inv</sub>/+, RC::epe+, Emx1<sup>CreEScre</sup>+) each resulted in the expected Mendelian ratios (one-fourth for each including genotypes that contained either one or two RC::epe alleles) (Fig. 6A).

Embryo processing for whole-mount and section X-gal staining of gene trap embryos or pups
Embryos and newborn P0 pups were generated through intercross timed matings between carriers of one of the three Prdm16 cGT allele variants. Females were inspected for the presence of a post-copulatory vaginal plug each morning: noon on the day the plug was identified was considered E0.5. Embryos were dissected via post-mortem cesarean section, and yolk sac or tail tissue was removed for DNA isolation and genotyping. Embryos to be used for histological analysis were fixed with Bouin’s fixative for at least 48 h, rinsed thoroughly in multiple changes of 70% ethanol and processed for paraffin embedding either manually or with the use of a Leica TP1020 automated tissue processor. Sections were cut at a thickness of 7 or 10 μm and stained with hematoxylin and eosin using standard protocols. Whole-mount and section X-gal staining was performed as described (Nagy et al., 2003). E10.5 embryos were fixed in 2% formaldehyde, 0.2% glutaraldehyde for 30 min on ice, E13.5 embryos for 1 h and P0 brains for 1.5-2 h. For X-gal staining of sections, samples were infused with 30% sucrose for at least 24 h, followed by cryoembedding in OCT and cutting into 15 μm sections for staining.

Skeletal preparations
Newborn wt and Prdm16<sup>GT</sup> mutant embryos were collected, skimmed and viscereated before placement into 95% ethanol for at least 1 day. All steps were performed with slow rocking at room temperature. Ethanol was replaced with Alcian Blue staining solution (0.03% Alcian Blue, 80% ethanol, 20% acetic acid) for 2-3 days, followed by a 6-12 h wash in 95% ethanol. Ethanol was replaced with 2% KOH solution for 24 h or until the tissue was appropriately cleared, followed by staining in Alizarin Red solution (0.03% Alizarin Red, 1% KOH, water) for 24 h. Skeletons were cleared in 1% KOH/20% glycerol solution and transferred to 1:1 glycerol:95% ethanol solution. E14.5 embryos were collected and placed immediately into 95% ethanol for at least 1 day. Staining was performed as described above but with reduced time at each step. Images were captured as described previously and using the Leica Montage module within the Leica application suite (LAS) software package.

Micro-computed tomography (μCT)
Newborn heads were harvested and processed as described for the immunolabeling experiments in the brain. The mice crania were scanned using a Skyscan 1272 μCT system housed at the University of Iowa College of Dentistry. To provide sufficient resolution and image quality, we used a 360° scan protocol at 70 kv and 142 mA with an 18-μm voxel size (resolution). Scans were acquired using a 0.5 mm aluminum filter with a rotation step of 0.6°. These parameters were selected to optimize scan resolution, image quality and scan time. Images were decimated and visualized using Geomagic Studio 2014 (www.3dsystems.com). Three-dimensional volume-rendered models of each cranium were created from the μCT image stacks [3D Slicer v 4.6 (www.slicer.org)].

Microscopy and imaging
Gross, whole-mount stained and fluorescent embryos and skeletal preparations were visualized using a Leica M165 C stereodissecting microscope equipped with fluorescent capabilities. Stained embryo sections were visualized using a Leica DM 5500 B upright compound light microscope. Digital images were captured using a Leica DFC 450 C color camera or Leica DFC 365 FX monochrome camera using LAS with the Montage module or LAS X software for fluorescence imaging.
Brain sample preparation for immunolabeling

Embryos and brains dissected from newborn pups were rinsed three times in PBT (PBS/0.1% Tween-20), followed by fixation by immersion in 4% paraformaldehyde in PBT and rinsing and storage in PBT/0.5% sodium azide. The fixed tissues were sectioned coronally (80-100 μM) using a vibratome (Leica Microsystems).

Immunofluorescence and confocal imaging

To stain with various antibodies, brain sections were incubated for 1 h at room temperature in blocking solution (10% FBS, 0.3% Triton X-100), then in the primary antibody at 4°C overnight. Sections were washed 3×20 min in 0.3% Triton X-100 in PBS, then incubated in Alexa-Fluor-conjugated or DyLight-conjugated secondary antibodies for 2 h at room temperature. Incubation with DAPI for 5 min and 3×20 min 0.1% Triton X-100 washes followed, both at room temperature.

Primary antibodies used in this study were: rabbit polyclonal anti-PRDM16 (1:500; Bjork et al., 2010) and goat anti-SOX2 (1:150; R&D Systems), mouse anti-TUJ1 (1:1000; Millipore), rabbit anti-Ki67 (1:500; Abcam) and rabbit anti-Caspase-3 (1:200; Cell Signaling). The secondary antibodies used were: donkey anti-rabbit-647 (1:1000; Jackson ImmunoResearch), donkey anti-goat-549 (1:1000; Immunoresearch) and donkey anti-mouse-647 (1:1000; Jackson ImmunoResearch). Imaging was done on a Leica CTR6500 confocal laser-scanning microscope. Velocity (Improbvision) and Photoshop (Adobe systems) softwares were used for image processing.
