Postnatal maternal separation modifies the response to an obesogenic diet in adulthood in rats

Laura Paternain1, Eva Martisova2, Fermín I. Milagro1, María J. Ramírez2, J. Alfredo Martínez1 and Javier Campión1,*

SUMMARY

An early-life adverse environment has been implicated in the susceptibility to different diseases in adulthood, such as mental disorders, diabetes and obesity. We analyzed the effects of a high-fat sucrose (HFS) diet for 35 days in adult female rats that had experienced 180 minutes daily of maternal separation (MS) during lactancy. Changes in the obesity phenotype, biochemical profile, levels of glucocorticoid metabolism biomarkers, and the expression of different obesity- and glucocorticoid-metabolism-related genes were analyzed in periovaric adipose tissue. HFS intake increased body weight, adiposity and serum leptin levels, whereas MS decreased fat pad masses but only in rats fed an HFS diet. MS reduced insulin resistance markers but only in chow-fed rats. Corticosterone and estradiol serum levels did not change in this experimental model. A multiple gene expression analysis revealed that the expression of adiponutrin (Adpn) was increased owing to MS, and an interaction between HFS diet intake and MS was observed in the mRNA levels of leptin (Lep) and peroxisome proliferator-activated receptor gamma coactivator 1 alpha (Ppargc1a). These results revealed that early-life stress affects the response to an HFS diet later in life, and that this response can lead to phenotype and transcriptomic changes.

INTRODUCTION

Obesity is defined as a disproportionate accumulation of body fat mass, which is normally accompanied by an excessive increase in body weight, making this chronic disease one of the most serious public health problems around the world (Martí et al., 2008). The rapid increase in the prevalence of obesity is not only attributable to genetic causes (Moleres et al., 2009) or to adult lifestyle factors such as lack of physical exercise and consumption of high fat and high glycemic index diets (Astrup et al., 2008), but also to early-life determinants and epigenetic marks that are increasingly recognized as being of great importance (Cagampang et al., 2011).

The postnatal environment plays a relevant role in neurodevelopment and behavioral responses later in life (Maniam and Morris, 2010). Indeed, several animal studies and human epidemiological data support the notion that fetal programming and neonatal events can have long-term or permanent effects. These become characteristic of the individual (Loizzo et al., 2006), because a stressor acting in critical periods during early life can alter structure, physiology and metabolism, causing permanent dysfunctions (Godfrey and Barker, 2001). Moreover, an adverse early-life environment has been postulated to be involved in the susceptibility to different diseases in adulthood, such as mental disorders, cancer, diabetes mellitus and obesity (Burdge et al., 2009).

In this context, maternal separation (MS) is a well-known animal paradigm (Levine, 2002; O’Mahony et al., 2009), resulting in animals with behavioral and neuroendocrine signs of elevated stress reactivity as adults (Aisa et al., 2007; Ladd et al., 2000; Solas et al., 2010).

Furthermore, it has been described that stress can reduce body weight in rodents (García-Díaz et al., 2007; Lin et al., 2005; Marín et al., 2007; Paternain et al., 2011), but there are controversial results in experimental studies combining a hypercaloric diet and stress (García-Díaz et al., 2007; Isingrini et al., 2010; Kamara et al., 1998; Kuo et al., 2008; Kuo et al., 2007; Levin et al., 2000; Pecoraro et al., 2006; Tamashiro et al., 2007). These contrasting outcomes might be caused by the paradigms used, but also might depend on the species and strains or the type and composition of the diet. In this sense, it has been extensively reported that adverse behavioral actions and obesity are related to hypothalamic metabolism (Torres and Nowson, 2007), but little is known about the peripheral processes by which these factors affect adiposity and insulin resistance (Kuo et al., 2007). Based on this background, in the present work we have evaluated the peripheral effects of high-fat sucrose (HFS) diet intake on adult female rats that had experienced MS.

RESULTS

Effects of an HFS diet and MS on body weight gain and other corporal measurements

In adult rats, HFS diet intake induced the expected overweight model and this effect was reflected in a higher body weight gain ($F_{3,33}=49.04$, $P<0.001$; $n=6-11$), final body weight ($F_{3,33}=16.112$, $P<0.001$; $n=6-11$), food intake ($F_{3,33}=12.436$, $P<0.05$; $n=2-3$) and energy efficiency ($F_{3,33}=23.182$, $P<0.001$; $n=6-11$) (Table 1). Regarding adiposity, there were significant increases in visceral fat (calculated as the sum of periovicar, retroperitoneal and mesenteric fat pads; $F_{3,33}=26.279$, $P<0.001$; $n=6-11$) and total fat (calculated as the sum of visceral and subcutaneous fat pads; $F_{3,33}=27.069$, $P<0.001$; $n=6-11$), including all the analyzed depots separately [retroperitoneal white adipose tissue (WAT), $F_{3,33}=50.754$, $P<0.001$; $n=6-11$; subcutaneous WAT, $F_{3,33}=26.861$, $P<0.001$; $n=6-11$; mesenteric WAT, $F_{3,33}=32.222$, $P<0.05$; $n=5-11$; periovicar WAT,
F_{3,32}=23.803, P<0.01; n=6-10) (Fig. 1). The MS paradigm during lactation reduced overall fat depots in adulthood without modifying food intake (Kcal/day) (Fig. 1B-F) except for the retroperitoneal WAT depot (Fig. 1A), although this reduction did not reach statistical significance. This effect of early-life environment on adiposity was independent of HFS diet for mesenteric depot and dependent on HFS diet intake for subcutaneous (F_{3,33}=5.580, P<0.05; n=6-11) and periovaric (F_{3,33}=4.217, P<0.05; n=6-10) depots (Fig. 1D,E).

**Effects of an HFS diet and an early-life stress on biochemical overweight biomarkers**

Biochemical measurements at the end of the dietary treatment confirmed that the HFS diet induced different abnormalities leading to the common features associated with obesity and metabolic syndrome in rats, such as higher serum leptin levels (F_{3,32}=27.231, P<0.001; n=6-11) and glucose levels (F_{3,33}=8.142, P<0.01; n=6-11), and lower serum triglyceride (F_{3,33}=12.870, P<0.05; n=6-11), cholesterol (F_{3,3}=17.853, P<0.001; n=6-11), high-density lipoprotein (HDL; F_{3,3}=22.114, P<0.001; n=6-11) and free fatty acid (FFA; F_{3,3}=15.479, P<0.001; n=5) levels (Table 2).

With regard to insulin resistance biomarkers, there was an interaction between the dietary treatment and MS paradigm in serum insulin levels (F_{3,30}=9.376, P<0.01; n=5-11), as well as in the homeostasis model assessment (HOMA) index (F_{3,30}=6.685, P<0.05; n=5-11). Further analysis revealed a significant decrease in insulin resistance markers in chow-fed rats only. Finally, neither HFS diet intake nor MS protocol induced significant changes during fasting state on serum corticosterone levels and estradiol levels, measured as biomarkers of the hypothalamic adrenocortical axis, or in serum MCP-1 levels, assessed as an inflammation marker.

**Effects of an HFS diet and MS on gene expression in periovaric WAT**

The analysis using a fold-change cut-off of 1.5 of the reverse-transcriptase PCR (RT-PCR) array in a small sample (n=20) showed up to 9 of 52 mRNA values as relevant in the study (supplementary material Table S1). However, after the validation of these 9 genes in the whole sample (n=34), up to 3 of 9 mRNA values were considered as differentially expressed due to an HFS diet, MS or both together (Table 3). Thus, the HFS diet in rats over 5 weeks induced an increase of Ppargc1a (F_{3,30}=16.678, P<0.001; n=6-11)

and Lep (F_{3,32}=22.94, P<0.001; n=6-11) mRNA levels (Table 3). Furthermore, a statistically significant increase due to MS was observed in Adpn (F_{3,32}=5.58, P<0.05; n=6-11), and a decrease in Ppargc1a (F_{3,30}=11.93, P<0.01; n=6-11). Moreover, statistical interactions were observed between an HFS diet and MS in Lep mRNA levels (F_{3,32}=5.58, P<0.05; n=6-11) in association with the fat pad masses, and Ppargc1a (F_{3,30}=13.17, P<0.01; n=6-11).

**DISCUSSION**

In the current trial, we evaluated the peripheral effects of an HFS diet in female rats that had experienced an MS paradigm. Gender is one major variable that appears to confer differential vulnerability to stress. As Verbruggen (Verbrugg, 1985) and Frankenhaeuser et al. (Frankenhaeuser et al., 1976) reported, men and women differ in physiological and behavioral responses to stressors and in epidemiological patterns of stress-related illness. Despite the knowledge that women are more susceptible than men to stress-related mental illnesses such as major depression (Lewinsohn et al., 1998; Swaab and Hofman, 1995; Weinstock, 1999), many of the relevant studies in this field have been conducted in males, and less information is available on the response of female rodents to stressors. Sex differences in sensitivity to stress have also been documented in animals (Brown et al., 1996; Taylor et al., 2000) and there is no doubt that females are affected by some early environmental manipulations (Nunez et al., 1995). As expected, the intake of the hypercaloric diet induced changes in various obesity-related phenotypic and biochemical parameters (Milagro et al., 2006). Thus, increases in body weight and food intake in HFS-diet-fed groups were observed, together with higher fat pad mass and lower serum triglyceride, HDL and FFA levels. These results are in agreement with other studies, which have shown that the decrease in the lipid profile observed is characteristic of the rat models (Boque et al., 2009; Lomba et al., 2010). Moreover, serum leptin, an accurate obesity biomarker (Martí et al., 1999), was increased owing to the diet. Remarkably, the dietary treatment did not affect adiponectin, MCP-1 (one of the key factors involved in the initiation of obesity-related inflammation) (Melgarejo et al., 2009) or insulin resistance biomarkers. However, some studies (Galipeau et al., 2002; Horton et al., 1997) have reported that female rats are protected against the metabolic defects typically produced by high-carbohydrate feeding, which is also in agreement with previous work published by our group (Lomba et al., 2010). In the present work, the nutrigenomic study involving the analysis of the expression of 52 genes in periovaric WAT and the subsequent validation highlighted some mechanisms related to diet-induced obesity. Interestingly, only two genes were significantly affected by the HFS diet: Ppargc1a and Lep. The small number of

changed genes could be explained by the animals’ adaptation to the diet, as Fearnside et al. suggested (Fearnside et al., 2008).

As expected (Roberts et al., 2002), owing to the diet, *Lep* mRNA levels were increased in periovaric WAT, although no changes were observed in either *Cecl2* or *Adipoq* mRNA levels. *Ppargc1a*, encoding a molecule involved in thermogenesis (Yudkin et al., 1999), was decreased by an HFS diet, which is in agreement with Arçari et al. (Arçari et al., 2009), who described that PGC-1α is downregulated by a high-fat diet.

In the scientific literature, there are contradictory results on the effect of a high-fat diet on the expression level of genes related to the metabolism of glucocorticoids in WAT. Thus, some studies have reported no changes in the levels of 11βHSD-1 or glucocorticoid receptor (GR) (Drake et al., 2005), some a decrease in 11βHSD-1 expression and activity (Livingstone et al., 2000) and another an increase (Walker, 2007). In this study, no changes were observed in any of the genes that we studied related to the metabolism of glucocorticoids. For blood corticosterone after a high-fat diet, the same conflicting outcomes have been reported, such as a lack of effect, as in this trial (Campion and Martinez, 2004; Maniam and Morris, 2010) or a decrease in the circulating levels of this hormone (Drake et al., 2005). Despite these differences, Maniam and Morris found that glucocorticoid response is blunted by the high-fat diet in rodents (Maniam and Morris, 2010), suggesting alterations in the hypothalamic-pituitary-adrenal (HPA) axis. Thus, Drake et al. have described that a high-fat diet reduces glucocorticoid concentrations, and that this is a key mechanism protecting against the metabolic complications of obesity (Drake et al., 2005).

The MS model in rats is considered a robust model of enhanced stress responsiveness (Aisa et al., 2007; Ladd et al., 2000; Levine, 2002; O’Mahony et al., 2009; Solas et al., 2010). This model has been associated with the development of anxiety-like behavior and learning impairments in adult rats. Moreover, different clinical and experimental studies have demonstrated that there is a clear relationship between the fetal environment and the risk of developing insulin resistance (Gluckman and Hanson, 2004). Furthermore, experiments in several animal species have shown an induction of insulin resistance and other manifestations of the metabolic syndrome by manipulating maternal nutrition or exposing the mother to synthetic glucocorticoids (Gluckman and Hanson, 2004). The MS paradigm decreased several fat pad masses and had a particularly remarkable effect in periovaric and subcutaneous WAT, suggesting that a neonatal adverse experience could lead to a different response to a hypercaloric diet intake in adulthood, compared with the control group. Curiously, no changes were found in food intake due to MS, indicating that the decrease in WAT weights could be due to previous modifications in peripheral tissues during lactation (De Moura and Passos, 2005). Thus, stress has been linked to obesity mainly through hypothalamic effects on food intake or peripherally through β-adrenergic (Troisi et al., 1991), glucocorticoid (Rosmond et al., 1998) or parasympathetic (Bartness et al., 2005) activity. As Kuo et al. stated (Kuo et al., 2007), in response to a stressor, some people lose weight, mainly via the β-adrenergic-mediated lipolytic pathway, whereas others gain weight, increasing the adipose tissue levels of cortisol, which could upregulate the expression level of neuropeptide Y (NPY) in the sympathetic nerves, stimulating the proliferation, differentiation and lipid filling of adipocytes.

Moreover, the developmental plasticity, which is an adaptive process enabling an organism to respond to environmental insults acting in early life, could be reinforced by epigenetic mechanisms, such as DNA methylation and histone modifications (Cordero et al., 2011; Gluckman, 2011).

There is no consensus in the literature concerning the effect of neonatal manipulations on baseline corticosterone levels. Thus, some studies have found no differences (Kim et al., 2005; Ladd et al., 2004; Maniam and Morris, 2010), whereas others report decreased (Panagiotaropoulos et al., 2004; Papaoannou et al., 2002) or increased (Kawakami et al., 2007) corticosterone levels. In this sense, we did not observe any change in serum corticosterone levels; this lack of response could be attributed to the alteration by MS of the responsivity of the HPA axis to fasting (Kim et al., 2005). However, Aisa et al. reported a depressive-like behavior and increased axis responsiveness to acute stressors in female rats subjected to exactly the same MS paradigm (Aisa et al., 2008). Moreover, the behavioral test of males from the same litter of our rats demonstrated a hyperactivation of the HPA axis (Martisova et al., 2012), indicating that the rats of this trial might also have an altered HPA axis.

Regarding the effects of MS on the serum biochemical measures, all insulin resistance biomarkers were decreased owing to MS, but only in chow-fed rats, in accordance with previous studies (Delaunay et al., 1997; Lambillotte et al., 1997; Solas et al., 2010), which reported that glucocorticoids inhibit insulin secretion from pancreatic β-cells.

The nutrigenomic study showed a significant increase due to MS in *Adpn*, which is an adipose-specific transmembrane protein regulated by energy balance (Baulande et al., 2001) and which has been postulated to be part of the adipose-specific energy homeostasis sensor (Johansson et al., 2006), and a decrease in *Ppargc1a* (Carbone et al., 2012). Glucocorticoids are widely mentioned as triggering both lipolysis and adipogenesis, depending on the concentration, duration and type of glucocorticoid investigated, as well as the experimental model used (Kershaw et al., 2006; Masuzaki et al., 2001; Xu et al., 2009). Moreover, Yu et al. (Yu et al., 2010) and Campbell et al. (Campbell et al., 2011) reported that glucocorticoids could stimulate adipogenesis by acting on preadipocytes, and concomitantly could increase lipolysis through actions on mature adipocytes.

Estrogens might alter or interact with the HPA axis in regulating corticosterone release and in influencing cognitive function, and it has been suggested that estrogen in females might protect against the effects of corticosterone (Luine, 2002). However, in this study we did not observe any statistical change between the groups.

Our results suggest that early adverse events can lead to biological changes in the pups that persist into adulthood, inducing a different response to an HFS diet in later life involving alterations in the lipolysis and lipogenesis pathways. These changes could be explained via epigenetics, because DNA methylation and histone code could be modified during MS (Franklin et al., 2010) and these could be responsible for the different outcome induced by the HFS diet in this trial.

METHODS

Animals and experimental design

Timed-pregnant Wistar rats on gestation day 16, supplied by Charles River Laboratories (Barcelona, Spain), were individually...
housed in a temperature (21±1°C)- and humidity (55±5%)-
controlled room on a 12-hour light-dark cycle with food and water
freely available. As previously described (Aisa et al., 2007), on
postnatal day (PND) 2, all pups were sexed and litters were
randomly assigned to the control group (NH; n=3), for which pups
were only briefly manipulated to change the bedding in their cages
once weekly, or the separation group (S; n=4), for which pups were
daily separated from their dam for 180 minutes from PND2 to 21
inclusive. Before manipulation of the MS pups, each dam was
removed from her home cage and placed in an adjacent cage, then
the pups were removed as complete litters, placed in an empty cage
with standard bedding material and transferred to an incubator in
an adjacent room. To compensate for the mother’s body heat,
the temperature of the incubator was adjusted according to the age
of the neonates: 32±0.5°C (PND2-5), 30±0.5°C (PND6-14) or 28±0.5°C
(PND15-21). Rats were weaned on PND23 and only females were
chosen for the present study. All subsequent experiments were
performed when the rats were adult (60-75 days).

At 2 months of age, NH and S animals were randomized by
weight into two dietary groups: standard chow diet (2014 Tekland
Global 14% Protein Rodent Maintenance Diet, Harlan Iberica,
Barcelona, Spain; C group, n=6 and MS group, n=10) and HFS diet
[20% protein, 35% carbohydrate, of which 17% was sucrose, 45%
fat, from Research Diets, Inc. (D12451); HFS, n=7 and HFS-MS
group, n=11]. Animals were randomized to ensure that, in most
cases, in each dietary treatment there were only three rats from
each litter. Animals had ad libitum access to water and food during
the experimental trial (35 days), and body weight was recorded
twice a week. After animals were sacrificed by decapitation,
bleeding and tissue samples were immediately collected and frozen
(−80°C) for further analysis. All procedures were performed
according to national and institutional guidelines of the Animal
Care and Use Committee at the University of Navarra.

Serum measurements

Circulating glucose was measured with an HK-CP kit (ABX
Diagnostic, Montpellier, France) in automated COBAS MIRA
equipment (Roche, Basel, Switzerland). Serum leptin (Linco
Research, St Charles, MO), adiponectin (Linco Research, St Charles,
MO), insulin (Merckodia AB, Uppsala, Sweden) and MCP-1
(Invitrogen, Carlsbad, CA) levels were determined by ELISA using
automated TRITURUS equipment (Grifols International S.A.,
Barcelona, Spain). The HOMA, an index that estimates the insulin
resistance based on the relationship between the fasting plasma
insulin concentration and glucose concentration, was calculated as:
[fasting plasma glucose (mM) × fasting serum insulin
(μU/ml)]/22.5, as described elsewhere (Paternain et al., 2011). The
homeostasis model of assessment of β-cell function (HOMAβ) was

calculated as: [(fasting serum insulin (μU/ml) × 20]/[serum glucose
(mM) − 3.5] (Bianchi et al., 2010). The quantitative insulin
sensitivity check index (QUICKI) was calculated as the inverse of
the sum of the logarithms of the fasting insulin and fasting glucose
(Cacho et al., 2008). Serum corticosterone level was determined
using a commercially available enzyme immunoassay kit (IDS,
Boldon, UK). Serum estradiol levels were analyzed on the Immulite
2000 analyzer by a competitive immunoassay using the reagents
and calibrators supplied by the manufacturer (Diagnostic Products
Corporation).

Real-time PCR

Total RNA was isolated from periovaric WAT from the whole
sample (n=35), according to Trizol manufacturer’s instructions
(Invitrogen, Carlsbad, CA), followed by an additional purification
step using the RNA easy kit (Qiagen, Germantown, MD). cDNA
was synthesized using the RT2 First Strand Kit (Qiagen,
Germantown, MD).

From the 35 animals included in the study, 20 (n=4 per
experimental group) underwent analysis using a quantitative real-
time PCR array (RT-PCR array) of 52 recognized genes related to
obesity and glucocorticoid metabolism (supplementary material
Table S2) following the manufacturer’s recommendations using the
ABI PRISM 7900 HT Fast Real-Time PCR System (Applied
Biosystems, Austin, TX). Obesity-related genes were analyzed with
RT2 qPCR Primer Assay (Qiagen, Germantown, MD), whereas
glucocorticoid metabolism genes were examined with Taqman
probes for rats (Applied Biosystems, Austin, TX).

For the validation of the RT-PCR array, nine genes were selected
and analyzed in the whole sample (n=35) using ABI PRISM 7900
HT Fast Real-Time PCR System (Applied Biosystems, Austin, TX)
and Taqman probes for rats (Applied Biosystems, Austin, TX):
Adpn (Rn 01502361_m1), Ccl2 (Rn 00580555_m1), Cd36 (Rn
00580728_m1), Lep (Rn 565158_m1), Lipe (Rn 00563444_m1), Mgll

Clinical issue

Postnatal exposure to stress is thought to increase the level of hormones and
affect metabolic pathways that alter physiology, metabolism and brain
structure, potentially causing permanent dysfunction. Increasing evidence
indicates that such changes can influence the development of diseases –
including metabolic diseases such as obesity and diabetes, as well as mental
illnesses such as depression and anxiety – in adulthood, reducing quality of life
and life expectancy.

Results

In this paper, the authors tested the effect of postnatal stress (maternal
separation) on the susceptibility of adult rats to diet-induced metabolic
disease. They find that rats that experience maternal separation during the
lactating period show a differential response to a high-fat sucrose (HFS)
diet in adulthood, compared with controls. Postnatal maternal separation
reduced the weight of certain adipose depots, but only in rats fed an HFS diet.
Postnatal maternal separation reduced serum insulin levels and the HOMA
index (a measure of insulin resistance), but only in rats fed a normal diet.
Analyses of 52 genes related to obesity and glucocorticoid metabolism
revealed altered expression of three key metabolic genes: adiponutrin (Adpn)
was increased by maternal separation, whereas alterations in leptin (Lep) and
peroxisome proliferator-activated receptor gamma coactivator 1-alpha
(Ppargc1a) were affected by the combined effect of maternal separation and
an HFS diet.

Implications and future directions

This study reinforces the idea that a stressful early-life environment can
critically affect adult health. The results provide candidate genes that are
influenced by the postnatal environment and that are involved in the response
to an obesogenic diet in later life. Future studies should analyze the regulation
of additional genes related to obesity metabolism in greater detail, as well as
investigate potential epigenetic changes caused by maternal separation and a
hypercaldoric diet. A greater understanding of how early-life stress affects
metabolism might help to develop nutritional strategies that overcome the
negative effects of early-life stress in adulthood.

Maternal separation and diet-induced obesity in adult rats
